

ELECTRICAL CONNECTIONS IN SUBSTRATES

Field of the Invention

5 The present invention relates generally to the field of semi-conductor technology, and in particular to a method of making a product, usable as a starting substrate for the manufacture of a large variety of semi-conductor devices. It also relates to the product as such.

Background of the Invention

10

In many applications in the semi-conductor industry (in a broad sense including both micro-electronics, micro-optics and micro-mechanics) it is often required to build components on both sides of a semiconductor wafer, such as a silicon wafer, for the manufacture of semi-conductor devices, such as sensors, micro-mirror arrays, just to mention a few.

15

In the prior art for packaging and interconnecting such devices wire-bonding has been the common technique. However, wire bonding is not cost-effective and for devices requiring many interconnection wires, such as array devices, it may not be possible to attach wires at all. Therefore, over the last decade so called flip-chip mounting has been widely used for electronic components, to avoid the need of wire bonding, thereby allowing for simplification, improved quality and cost reduction in the back-end packaging/interconnection process. However, flip-chip bonding connects the device with "front-side" down. This is most often not possible for MEMS devices (MEMS = Micro-Electrical-Mechanical Systems), for example sensors and micro-mirrors, which need to have the front-side up.

25

Other techniques in this field have been based on the provision of metallized portions in holes extending through a wafer, for the purpose of establishing electrical contact between the two surfaces.

30 Such mixing of materials (i.e. metals and semiconductor material of the wafers) puts limitations on the subsequent processes that can be utilized for the manufacture of components, in terms of usable temperatures and chemical environments.

One method of the just mentioned kind is disclosed in US-6,002,177.

35

A further method is disclosed in WIPO publication WO 01/65598 A1 (corresponding to published US patent application 2003/0022475 A1), by Vieux-Rochaz et al.

5 The method in the latter document comprises the provision of grooves on one side of a wafer, the grooves defining suitable closed patterns, e.g. rings, squares rectangles etc., filling the grooves with insulating material, building components matching the enclosed areas, making a plurality of second grooves from the bottom surface mating with the top grooves, filling said second grooves with insulating material, and building components on the bottom surface, using the thus formed electrical connections to connect the top and bottom components as
10 desired.

This process is fairly complex, and the publication does not disclose the manufacture of a platform comprising electrical through connections (vias), and usable as a generally applicable starting substrate for semi-conductor applications.

15

Summary of the Invention

Therefore, the object of the present invention is to provide a method of making a generally applicable starting substrate for semi-conductor manufacture applications, allowing full
20 utilization of common process technology in this field, without any restrictions in process parameters.

This object is achieved with a method according to claim 1. Thereby, there is provided a method of making an electrical connection between a first (top) and a second (bottom) surface
25 of a conducting or semi-conducting substrate, comprising creating a trench in the first surface; establishing an insulating enclosure entirely separating a portion of said substrate, defined by said trench, from surrounding material of said substrate, but exposing the top and bottom surfaces of said separated portion.

30 In a further aspect of the invention there is provided a platform product for semi-conductor manufacture applications, comprising a wafer of a conducting or a semi-conducting material, and having well defined electrical through connections (vias).

Such a product is defined in claim 14.

35

The present invention with wafer through electrical interconnection vias allows "flip-chip packaging" without flipping the front-side downwards since the solder bumps for flip-chip mounting could be placed on the backside of the (MEMS) device.

5 **Brief Description of the Drawings**

The invention will be described below with reference to the drawings, in which

- 10 Fig. 1a is a schematic perspective view of a wafer having vias of the invention;
 Fig. 1b is a schematic cross section of a wafer as in Fig. 1;
 Fig. 2a shows a cross section of a wafer before processing;
 Fig. 2b illustrates a wafer with trenches in cross section;
 Fig. 2c shows a wafer with trenches filled with oxide;
15 Fig. 2d shows an embodiment where trenches have been filled by oxidation and
 deposition;
 Fig. 2e illustrates a trench exhibiting a narrowed opening;
 Fig. 3 shows various possible geometrical shapes of trenches;
 Fig. 4a illustrates a further embodiment of the method according to the
 invention;
20 Fig. 4b is a cross section of a wafer having vias made according to the further
 embodiment of the invention;
 Fig. 5a illustrates another embodiment of the method of making vias according
 to the invention;
 Fig. 5b shows the result of the method according to Fig. 5a;

 having through connections ending in a cavity;

Fig. 13 illustrate a similar process to the one of Fig. 12, but wherein the starting material is an SOI wafer.

Detailed Description of Preferred Embodiments of the Invention

5

The invention in its broadest aspect is schematically illustrated in Figs. 1a and b (not to scale). It comprises a wafer 10 of a conducting or a semi-conducting material, forming a substrate suitable for the manufacture of a large variety of micro-electronic devices, an/or micro-mechanic devices, and/or micro-optical devices, requiring components on both sides of the
10 wafer, e.g. sensors, micro-mirror arrays, micro-optical components such as lasers etc.

The inventive feature is the provision of vias 12, or electrical through connections, extending from a top side 14 of the wafer 10 to a bottom side 16. By means of the method according to the invention the vias comprise the same material as the material of the wafer, i.e. they are
15 made from the wafer itself. Thus, no auxiliary material is used for the actual electrical connection.

In order to separate the vias 12 from the bulk 13 of the wafer in an electrically insulating manner, there is according to the invention oxide material 15 introduced between the bulk 13
20 and the vias 12. The method will be described in further detail below.

By virtue of the fact that only "wafer native" material is used, i.e. the material of the wafer itself is used to manufacture the vias, the wafer having been provided with said vias in a desired structure, can be subjected to all the processing steps employed in the semi-conductor
25 field, in terms of temperature, chemical environment, pressure etc, that a "native wafer" can be subjected to. Prior art devices (i.e. starting wafers for semiconductor electronics manufacture) comprising metallized portions, cannot be processed in the same versatile way, because the metallization will not withstand too high temperatures, or the chemical agents frequently used in etching and other procedures needed to make the desired electronic or
30 micro-mechanic structures.

Another advantage is that the wafer according to the invention is flat exhibiting a very low surface roughness, down to mirror appearance.

By “native wafer” and “native wafer material” we mean the material in the original wafer itself. “Auxiliary material” would therefore be any other material that has been added to the structure, such as a metal pad for connection purposes.

- 5 A “wafer” shall be taken to mean a general substrate usable as a starting material for e.g. MEMS applications. It is not necessarily completely flat, but can be provided with predefined structures such as depressions or other elements or members created by some process performed on the material from which the wafer is made.
- 10 In a first embodiment of the invention, illustrated in Fig. 2a – 2c (cross sections of a wafer during the different process steps; not to scale), the vias are made in a process characterized as comprising two general steps, namely provision of trenches and introducing insulating material into the grooves, and optionally filling the trenches, at least partially with oxide.
- 15 The starting material is a conducting or a semiconductor wafer 20 (Fig. 2a), suitably a silicon wafer (although there are no specific limitations on the materials used), having a thickness of 500 μ m, although the thickness can vary between 300 μ m and 1000 μ m. Most commercially available silicon (or other semi-conductor) wafers are about 300-1000 μ m thick, depending on size and intended application. However, the invention is applicable to wafers exhibiting a
- 20 thicknes of 200 – 5000 μ m, preferably 300 - 3000 μ m, most preferably 400 - 1000 μ m.

The first general step is the provision of a trench 21, i.e. a narrow recess encircling a portion of the wafer top surface. The trench is made for example by etching or by laser based machining, or by EDM (electro-discharge machining).

- 25 Trench definition is achieved by providing a lithographic mask 22 (Fig. 2b) on the wafer, which in itself does not form part of the invention. It is considered to pertain to the field of the skilled man to design and use suitable masking and etching techniques, given the materials used. Thus, a detailed discussion of the provision of the mask is not given herein.

- 30 Preferably trenches are made by any etching method yielding a high aspect ratio, e.g. DRIE (Dry Reactive Ion Etching), electrochemical HF etch.

- 35 The trench should be less than 20 μ m, preferably 4-15, most suitably about 6-12 wide. Thus, the layers of insulating material are 1-20 μ m, typically 6-12 μ m thick.

If the wafer is 500 μ m thick, the trench is suitably about 200-490 μ m, preferably 300-400 μ m deep. Suitably the depth of the trench is about 50% up to 100% of the wafer thickness. In the case of 100% penetration, it is necessary that a thin oxide layer be present on the surface, to keep the formed "plug" in place.

With the method according to the invention, the pitch (center-to-center) distance between the electrical connections can be as small as 10 μ m, typically 50-100 μ m. If there is a thin oxide layer provided on the bottom surface, the etch can be all the way through the wafer until the etch reaches the oxide, which acts as an etch stop. Thereby the via, i.e. the cylindrical plug (in the case of circular etch trench), will be supported by the oxide and prevented from falling out.

The shape of the portion encircled by the trench can be circular, but is of course not limited thereto. Any geometric shape that can be achieved is possible, such as squares, rectangles, triangles, romboids, trapezoids etc. or combinations of shapes (Fig. 3). The only limitation regarding the obtainable shapes is set by any inherent limitations of the masking and etching procedures employed.

Once the trench is made, the mask is removed, and the wafer is subjected to an oxidizing process in order to grow insulating oxide 24 in the trench (and on the surfaces of the wafer unless it is protected), Fig. 2c. This is achieved by increasing the temperature to about 800-1300°C, typically 1100°C, in an oxygen containing atmosphere. Optionally, the oxidizing process can be terminated before the trench is completely filled, and the remaining space can be filled with e.g. TEOS 26, in a deposition process, because of its good step coverage properties. However, any insulating material that is compatible with IC or CMOS processing conditions can be used. It is not even strictly necessary to fill the trenches; it will suffice if the material surrounded by the trench is kept at an insulating distance from the wall. This can be achieved by the very small bridging oxide portion at the bottom of the trench.

Frequently, when etching trenches having the high aspect ratio as in the present invention, the opening of the trench at the surface will be slightly narrower than the width about 5-10 μ m below the surface (See Fig. 2e). This phenomenon may cause the trench to become incompletely filled with oxide, thereby creating voids (air traps) which may cause problems in the further processing by IC, MEMS or CMOS techniques.

In order to remedy this problem, suitably the wafer is subjected to a further etch after the trench defining mask work on the top surface of the wafer has been removed. This etch will thin down the surface slightly and remove the narrowing edges, leaving only a strictly
5 “funnel” shaped trench cross section. The cross section after the etch is indicate with broken lines in Fig. 2e.

When the trench/trenches have been suitably filled with insulating oxide, to the rate of filling desired, the wafer, in a second step, is subjected to a thinning process. Thereby, the back side
10 of the wafer is thinned down, by grinding or etching or other suitable method, such that the insulating oxide present in the trench/trenches becomes exposed on the back side of the wafer (indicated with a broken line in Fig. 2d). This procedure yields a plurality of “plugs” extending through the wafer and comprising a material which is identical to the bulk material of the wafer. The plugs will be surrounded by insulating oxide in patterns defined by the
15 trenches. The surfaces of these plugs on the top and bottom of the wafer, separated by the insulating oxide from the surrounding wafer material, represent bonding areas, to which further electronic elements can be bonded by suitable bonding techniques.

For certain applications it is necessary to provide cavities in a wafer, wherein the bottom of
20 the cavity is provided with electrical connections. For such an application it will be sufficient to etch the surface selectively on those areas where said cavities are to be formed. Thus, the overall nominal thickness of the wafer can be maintained, and the etching to expose the insulating material, thereby creating the vias can be achieved only in said depressions.

25 An example is the provision of deflectable micro-mirrors, where the deflection is carried out electrostatically by applying a voltage to an electrode in a cavity below the deflectable mirror.

An embodiment of the invention for the above purpose will be described with reference to
Figs. 12 and 13 below.

30 In a second embodiment of the invention, illustrated in Figs. 4a-b, the vias are also made in a process comprising two general steps, the first step of which is identical to the first step of first embodiment, thus yielding trenches 41 filled with insulating material 42, such as oxide and optionally TEOS. Also in this embodiment, it might be sufficient to let the oxide in the
35 bottom of the trench function as a spacer to keep the “plug” free from the surrounding wall.

This embodiment is primarily used when it is desirable to have a thicker platform (wafer substrate) 40 for the further manufacture. Since a trench can be made to exhibit a depth of about 400 μ m, it will be possible to make substrates comprising vias, and having a thickness of up to about 800 μ m. However, if still thicker wafers, say up to 1000 μ m or more are required, the second etch from the bottom side, will generate wider trenches, since a deep trench will inevitably be wider at the opening than a shallow trench. Thus, in this embodiment, the thicker wafers will not be strictly symmetric in the sense that the vias will not exhibit the same appearance on both the top and bottom sides.

10 In the second step of the second embodiment, patterns 43 are defined by lithographic methods on the bottom surface, see Fig. 4a, said patterns matching the trenches defined on the top surface. This will require an alignment of the patterns. This is however not part of the invention per se, and alignment of patterns are considered to pertain to the field of the skilled man, and will not be further discussed herein.

15 Trenches are etched in the same way as the trenches on the top side (indicated with a broken line in Fig. 4a), until they meet the oxide in the trenches made in the first step of the procedure. The final structure is shown in Fig. 4b, wherein the vias are designated 44, and the insulating separating walls are designated 45.

20 In this embodiment a thinning of the wafer is avoided, but at the cost of further processing steps.

In a third embodiment (Figs. 5a – b), the first step of the method comprises etching trenches that extend all the way through the wafer. This means that the wafer 50 cannot be thicker than the maximum depth that is achievable by etching, i.e. about 400 μ m. However, in this case, in order that the vias will not fall out from the wafer, of course the trench pattern must not define closed structures. That is, each trench is represented by a “line” (see insert in Fig. 5a), having a beginning and an end, such as a semi-circle, or two legs of an angle. When the first trench 52, extending through the wafer has been made, oxide is introduced into the trench, possibly the trench is filled with oxide. Then, a second trench 54, matching the first so as to form a closed structure, i.e. a second semi-circle matching the first semi-circle is etched, and subsequently filled with oxide, if desired.

In principle the final shape can be achieved in several steps, which is still within the inventive concept, but for practical reasons a two-step procedure is the most appropriate.

A further feature of the invention is to provide selectively doped vias, i.e. the vias exhibit
5 higher conductivity than the bulk of the wafer. This can be achieved by exposing the wafer
60, after trenches have been made, but before the mask work 61 is removed, to a doping
process (see Fig. 6a). Doping material is thereby introduced (illustrated by arrows) into the
trenches 62 (forming e.g. a circular shape), where it penetrates the walls in the trench, and by
diffusion enters the material in the cylindrical plug and also in the wall surrounding the plug
10 to a depth of up to about 15 μm . A suitable exposure and annealing time will yield a fully
doped, thus highly conductive via, whereas the bulk of the wafer is non-doped. After
(optionally) filling the trenches with insulating material, the final structure will be a wafer
comprising a plurality of high conductivity vias, insulated by means of an oxide from the bulk
of the wafer which can be essentially non-conductive, except from a finite region close to the
15 insulating material surrounding the vias. Due to the limited penetration depth, vias up to 30 μm
in diameter can be made in the above indicated way. However, if a hole 63, having a diameter
corresponding to the width of a trench, i.e. 5-10 μm , is provided by etching in the centre of
the area surrounded by the trench, the doping can be performed both from the outer
circumferential trench and from the center hole. In this way the diameter of the fully doped
20 via can be increased to about 60 μm . In further embodiments it is possible to provide a
plurality of concentric trenches, thereby enabling the provision of vias exhibiting a diameter
as desired, theoretically exhibiting no limitations regarding size.

The vias resulting from the doping process is schematically illustrated in Fig. 6b, wherein
25 dope regions are shown with denser hatching (the penetration depth of doping in the bulk of
the wafer is shown with broken lines).

This feature will have utility in RF applications.

30 The invention will now be further illustrated by way of non-limiting examples.

EXAMPLES

Example 1 (prior art)

In fig. 7 a prior art electrical connection structure is shown (corresponding to Fig. 3 in US-6,002,177). It comprises drilling holes in a silicon chip and metallizing the internal walls of said holes to provide electrical connections between the two sides of the chip.

5 Example 2 (demonstration of problem with standard trench etch)

A standard trench etch was performed on a silicon wafer. The wafer was 100 mm in diameter and 500 μ m thick.

10 In order to provide the trenches, a patterned mask was provided on one surface (top surface) of the wafer, by standard lithographic technique. The trenches in this example were simple "line" shaped trenches.

The etching process was a so called DRIE (Deep Reactive Ion Etch)

15 A series of trenches exhibiting varying depth and width was made the depths varying between 200 and 400 μ m and the width between 5 and 12 μ m. In Fig. 8 a magnified view of the top opening of a trench is shown. As can be clearly seen, the opening is narrower than the trench about 10 μ m down in the trench. This phenomenon causes frequently an incomplete filling of
20 the trench in a subsequent oxide filling step.

Example 3 (elimination of the standard etch drawback)

Therefore, in order to remedy this problem, an additional, shallow etch as described in
25 connection with Fig. 2e was performed.

This process step yields a strictly monotonic trench shape, as can be seen in Fig 9a, i.e. the opening is the widest part of the trench, which then gradually becomes narrower. Fig. 9b shows the structure of a plurality of trenches after the shallow etch.

30 Filling this trench structure with oxide, will result in a completely filled trench with no voids.

Example 4

35 In Fig. 10 an example of an array of completed vias having a rectangular shape is shown.

Example 5

Fig. 11 shows an array of vias made according to the embodiment where etching from both
5 sides of the wafer has been employed.

Example 6

In Fig. 12 there is shown a schematic process sequence for making a MEMS device, in
10 particular an array of deflectable micro mirrors.

The starting substrate is an ordinary silicon wafer 70, Fig. 12a. Trenches 72 are etched to a
certain depth, as described above, and filled with oxide 74, see Fig. 12b. Then, a local area on
the opposite side of the wafer (with respect to the trenches) is etched to provide a depression
15 75 (or cavity), reaching down to where the trenches end, whereby the insulated (preferably
circular cylindrical through connections) are exposed, see Fig. 12c. A membrane or an array
of micro-mirrors, or some other suitable element or member (schematically indicated with
reference numeral 76 in Fig. 12c), as desired, is provided over the cavity, and the electrical
through connections can be used for actuating e.g. a deflectable membrane/mirror by applying
20 a suitable voltage. This can suitably be achieved by providing solder bumps 78 for flip-chip
mounting or metal pads for wire bonding, to provide connection to some power source or
other energizing device. Technology for manufacturing SLM's (Spatial Light
Modulators) whereby the present invention can be used, is disclosed in our pending US patent
application serial no. 10/654,007.

Example 7

In Fig. 13 a further embodiment of a process sequence for making a MEMS device is
schematically illustrated.

Thereby the starting material is a SOI wafer (Silicon On Insulator) 80, wherein an oxide layer
82 is buried inside a silicon wafer, Fig. 13a. Trenches 84 are etched and filled with oxide 86,
as described above, but due to the presence of the oxide layer, the trenches will only reach
exactly down to the oxide layer, which acts as an etch stop, Fig 13b. This is an advantage over
35 the embodiment of Fig. 12, wherein the bottoms of each trench may be located at slightly

different depths, such that when a depression is etched from the opposite side of the wafer, the through connections may extend slightly above the bottom surface of the depression. This is schematically illustrated in Fig. 12c, wherein it can be seen that there is a slight variation in how much each trench protrudes above the cavity bottom.

5

On the contrary, in the embodiment of Fig. 13, when the depression 88 is made by etching, first the buried oxide layer 82 will be reached, and then, when the oxide layer is removed, the trenches will be located exactly at the same level inside the depression, see Fig. 13c, or essentially “flush” with the bottom surface of said depressions. In fact, the trenches can be

10 “over etched” to ensure that all the trenches reach the same depth.

Thus, by the disclosure and examples given above, it has been shown that with the present invention, there is provided a product in the form of a starting substrate, in the form of a conducting or semi-conducting wafer, that can be used for the purposes of manufacturing a large variety of semi-conductor devices. By virtue of the wafer already from the start comprising electrical connections extending through the wafer (vias), it will become possible to design and make structures on both sides of the wafer in a very versatile way. The fact that the vias are made from the original wafer itself, makes the wafer capable of withstanding all process conditions usable with plain silicon wafers.
